(i): Reducing agent movement will decrease the height of infection peak and delay the timing of peak

why? I think fewer movements will decrease the probability of contacting and thus slowing/smoothing the infection transmission.

(ii): I expect individual runs to not look alike

why? I think initialization of agent's positions can significantly influence the simulation results

(iii): I expect the agent-based curves to resemble SIR curves

why? The well-established SIR model should be able to model such simple synthetic cases.
